Gas Exchange Detection of Exercise-Induced Right-to-Left Shunt in Patients With Primary Pulmonary Hypertension

Xing-Guo Sun, MD; James E. Hansen, MD; Ronald J. Oudiz, MD; Karlman Wasserman, MD, PhD

Background—Because of high pulmonary vascular resistance in patients with primary pulmonary hypertension (PPH), right atrial pressure may exceed left atrial pressure during exercise, resulting in a right-to-left shunt via a patent foramen ovale (PFO). This shunting would disturb arterial PCO₂ and H⁺ homeostasis if the pulmonary blood were not simultaneously hyperventilated to compensate for the high CO₂ and H⁺ in the shunted blood. This article first hypothesizes and then describes unique changes in gas exchange when right-to-left exercise-induced shunting (EIS) occurs.

Methods and Results—Retrospectively, the cardiopulmonary exercise tests of 71 PPH patients were studied. Criteria postulated to document hyperventilation of the pulmonary blood flow due to a right-to-left EIS were (1) an abrupt and sustained increase in end-tidal O₂ with a simultaneous sustained decrease in end-tidal CO₂; (2) an abrupt and sustained increase in the respiratory exchange ratio; and (3) usually, an associated decline in pulse oximetry saturation. Each patient was evaluated for a PFO with resting echocardiography. The investigators interpreting the gas exchange evidence of EIS were blinded to the echocardiographic readings. Forty-five percent of the patients had demonstrable EIS by gas exchange criteria. Almost all were also positive for a PFO by echocardiography. Using the resting echocardiograph as the reference, the sensitivity, specificity, positive and negative predictive values, and accuracy were all between 90% to 96%.

Conclusions—Exercise-induced right-to-left shunting can be detected by noninvasive, cardiopulmonary exercise testing in patients with PPH. (Circulation. 2002;105:54-60.)

Key Words: shunts ■ echocardiography ■ exercise ■ hypertension, pulmonary

Patients with right-to-left intracardiac shunts regulate arterial PCO₂ and pH by hyperventilating unshunted lung blood flow to compensate for the high CO₂ content in shunted blood.1 During clinical cardiopulmonary exercise testing (CPET) of patients with primary pulmonary hypertension (PPH), we frequently observed gas exchange patterns indicating acute hyperventilation of pulmonary blood flow, suggesting shunting via a patent foramen ovale (PFO).

In normal persons, right-to-left shunting via a PFO is unlikely because left atrial pressure exceeds right atrial pressure. However, with abnormally high pulmonary vascular resistance (as in PPH), right atrial pressure can exceed left atrial pressure, especially during exercise, and force venous (low Po₂ and high PCO₂ and H⁺) blood through a PFO directly into the systemic circulation, stimulating systemic arterial chemoreceptors and causing hyperventilation of the unshunted pulmonary blood flow. This compensatory hyperventilation increases CO₂ unloading, thereby maintaining arterial PCO₂ and H⁺ homeostasis, despite the presence of an exercise-induced right-to-left shunt (EIS).

The objective of the present study was to describe the specific gas exchange changes that can be used to identify those patients with PPH who develop an EIS.
Detection of EIS by Gas Exchange Criteria

Three author-investigators (graders), who were blinded regarding all identifying patient information and echocardiographic findings, independently reviewed the 9-panel CPET plots using the following criteria to identify an EIS at the start of unloaded cycling exercise:

1. An abrupt and sustained increase in end-tidal O₂ (PETO₂), with a simultaneous, sustained decrease in end-tidal CO₂ (PETCO₂) (Figure 1, panel 9);
2. An abrupt and sustained increase in the respiratory exchange ratio (RER = carbon dioxide elimination/oxygen consumption [V˙CO₂/V˙O₂]); Figure 1, panel 8), and
3. Usually, an associated SpO₂ decline (Figure 1, panel 9).

Echocardiography

All patients underwent resting transthoracic echocardiography with Valsalva maneuvers and bubble studies. The great majority had >1 echocardiogram on different days. In addition, ~1 of 10 had transesophageal echocardiography. If an atrial right-to-left shunt was detected during any echocardiographic study, the patient was categorized as PFO-positive (PFO⁺); if not, the patient was categorized as PFO-negative (PFO⁻).

Separation of PPH Patients into Groups

Using the above criteria applied to the 9-panel CPET graphic array, the 71 CPET studies were independently graded as either EIS-positive (EIS⁺) or EIS-negative (EIS⁻) by 3 graders. Two graders also used tabular data to aid in their decision-making when the changes in the graphic data were less obvious. Patients who were PFO⁺ by echocardiography and unanimously EIS⁺ were placed in the shunt group; those who were PFO⁻ by echocardiography and unanimously EIS⁻ were placed in the no-shunt group. Any PFO⁺ patient categorized as EIS⁻ or any PFO⁻ patient categorized as EIS⁺ by any grader was placed in the discordant group. During this process, all 3 graders independently identified 3 patients who were EIS⁻ during unloaded cycling but converted to EIS⁺ near the end of their CPET; these were excluded from the grouping.

Statistical Analyses

Data are expressed as mean±SD, except where specifically noted. Most CPET values are expressed as a percent of predicted value. Repeated ANOVA with 2-tailed Scheffe tests were used to identify differences between groups; paired t tests were used to identify changes from rest. P<0.05 was considered significant. Sensitivity, specificity, and predictive values of EIS detection of shunt were calculated, despite knowing that a PFO induced during exercise might be unrecognizable during resting echocardiography.

Results

Similarities of PPH Groups at Rest and Peak Exercise

All CPET studies were completed without adverse events. The demographics of the shunt, no-shunt, discordant, and
control groups were similar (Table 1). Except for a higher ventilatory equivalent for O$_2$ (Ve/VCO$_2$) at the anaerobic threshold and a higher slope of Ve versus VCO$_2$, all of the peak exercise CPET findings of the 3 PPH patient groups were similar to each other (Table 1) but dissimilar from findings in the control group.

### Differences in Gas Exchange Between Shunt and No-Shunt Groups

Figure 2 contrasts key CPET measurements that distinguish 2 representative PPH patients (one EIS+ and one EIS−) from a normal subject. Figure 3 describes the second-by-second mean values at rest and during the 3 minutes of unloaded cycling exercise for the same variables in the shunt, no-shunt, and control groups. In the PPH groups, gas exchange was impaired at rest (low PetCO$_2$ with high ventilatory equivalent for O$_2$ [Ve/VO$_2$], Ve/VCO$_2$, and PetO$_2$), with the PetCO$_2$ lowest in the shunt group (Figures 2 and 3). After beginning unloaded cycling, the shunt group abruptly decreased their PetCO$_2$, while the PetO$_2$, Ve/Vo$_2$, and RER concurrently abruptly increased (Figures 2 and 3). Shortly thereafter, the SpO$_2$ declined in most of the shunt patients. In contrast to the shunt group, the no-shunt group showed lesser changes in PetO$_2$, PetCO$_2$, RER, Ve/Vo$_2$, and SpO$_2$.

Table 2 summarizes the changes in PetO$_2$, PetCO$_2$, Ve/Vo$_2$, Ve/VCO$_2$, RER, Ve, and SpO$_2$ from rest to the end of unloaded cycling that distinguish the shunt group from the no-shunt group and the statistical significance of these changes. However, by the end of unloaded cycling, all groups had normal and similar increases in VO$_2$ and VCO$_2$.

### The Late-Developing EIS

Figure 4 depicts 1 of 3 patients who developed unmistakable gas exchange evidence of a late-developing EIS during CPET, just before stopping. As with an EIS during unloaded cycling, a late-developing EIS is characterized by abrupt and striking decreases in PetCO$_2$ and SpO$_2$, with concurrent striking increases in PetO$_2$, RER, and Ve/Vo$_2$ more than Ve/VCO$_2$. This patient was PFO− on repeated echocardiography. Her CPET pattern persisted until 2 years after starting epoprostenol therapy, at which time no further CPET evidence of EIS was noted, reflecting her improvement. The second patient had a similar late-developing EIS, but was PFO+ by echocardiography. The third patient with CPET changes typical of a late-developing EIS was PFO− on repeated echocardiography.

### Grouping of PPH Patients

Excluding the 3 patients with a late-developing EIS, Figure 5 shows the distribution of the 68 patients among the shunt (n=18) and no-shunt (n=39) groups (all 3 graders agreed) and the discordant group (n=11).

If the resting echocardiogram was used as a reference for PFO detection, the overall sensitivity and specificity for CPET EIS detection would be 90% and 96%, respectively (Table 3). Overall, PFO+ PPH patients would also be CPET EIS+ 94% of the time, whereas PFO− PPH patients would be EIS− 95% of the time. Within the discordant group, echocardiography documented a PFO in 6 patients (Figure 5), but 2 of them had been PFO− on one or more other echocardiographic studies, illustrating the inconstant nature of shunting, even at rest.

Considering all 71 PPH patients, 18 were early EIS+ (by all 3 graders) and PFO+; 6 others were PFO+ and EIS+ by the evaluations of 1 or 2 graders (Figure 5), and 3 others were late EIS+ by all 3 graders. Thus, 38% [(18+6+3)/71=38%] had convincing evidence for right-to-left shunting during CPET. Five others (Figure 5), although PFO−, had

Values are mean±SD. VO$_2$ indicates exercise oxygen uptake; %pred, percentage of predicted value; Ve, minute ventilation; MVV, directly measured maximal voluntary ventilation; AT, anaerobic threshold; Ve/Vo$_2$ at AT, ratio of ventilation to carbon dioxide output at anaerobic threshold.

*P<0.001, control group vs each group of PPH patients; †P<0.05, shunt group versus no-shunt group; all other comparisons, P>0.05 using 2-tailed repeated ANOVA.
Evidence suggesting that they were EIS+. Thus, up to 45% (127/27+32=71 = 45%) of our patients may have had right-to-left shunting during exercise.

Discussion
In the presence of a PFO and increased pulmonary vascular resistance, exercise-induced increases in venous return cause right atrial pressure to increase. When it exceeds left atrial pressure, venous return can shunt through a PFO, diverting deoxygenated, acidemic, CO₂-rich blood to the systemic circulation. This stimulates arterial chemoreceptors (carotid bodies) to maintain arterial H⁺ and PaCO₂ homeostasis, causing an immediate increase in ventilation, as manifested by rapid increases in alveolar PO₂ (reflected in a PETO₂ increase) and decreases in alveolar PCO₂ (reflected in a PETCO₂ decrease) (Figures 1 through 4). Consequently, CO₂ unloading from the unshunted pulmonary blood flow increases as alveolar PCO₂ falls, but O₂ loading increases less because pulmonary capillary O₂ reaches the flat part of the oxyhemoglobin dissociation curve. Thus, ventilation increases more steeply relative to VO₂ than VCO₂, resulting in a greater increase in Ve/VCO₂ than Ve/VCO₂ and a stepwise increase in RER (Figures 1 through 4).

Even at rest, there are distinctly more gas exchange abnormalities (higher Ve/VCO₂, Ve/NCO₂, and PETCO₂ and lower PETCO₂ and SpO₂) in the shunt than no-shunt groups (Figures 2 and 3). These pre-exercise abnormalities can be attributed to hypoperfusion of well-ventilated lung and probable chronic hyperventilation.2,5

With unloaded cycling, the group differences become more obvious (Figures 2 and 3 and Table 2). In the shunt group, Ve/VCO₂, PETCO₂, and RER all increased and PETCO₂ decreased (indicating an acute ventilatory increase disproportionate to metabolism), and SpO₂ decreased. In the no-shunt group, SpO₂ declined slightly. In contrast, Ve/VCO₂ and PETCO₂ decreased and PETCO₂ increased in the control group. An abrupt increase in Ve/VCO₂ always indicated an EIS in our study.

Figure 4 illustrates the concurrent, dramatic, unambiguous gas exchange findings seen when shunting abruptly begins and ends at the end of exercise rather than earlier. Near the end of exercise, the stimuli to the chemoreceptors (and oximeter probe) are robust because the shunted mixed-venous blood is more acidemic, hypercarbic, and hypoxemic; thus, it more strikingly alters ventilation to maintain arterial homeostasis.1

Pitfalls in Detection of a PFO and EIS
Because a PFO may be so small or the interatrial pressure differences so trivial, shunt blood flow may not be demonstrable by echocardiography, even with Valsalva maneuvers.6,10

During CPET, the shunt fraction may be so small or the data so noisy that interpretation of EIS criteria are ambiguous. Other potential problems for clinicians using CPET to detect an EIS include a delayed or imperfect response of the SpO₂ signal, a poorly scaled graphic data display, or a too-brief period of pre-exercise CPET data.

Two exercise-induced conditions that might lead the clinician to identify an EIS incorrectly are anxiety-induced hyperventilation or a very low anaerobic threshold.

Acute hyperventilation decreases PETCO₂ while increasing PETO₂, Ve/VCO₂, Ve/NCO₂, and RER. However, hyperventilation without shunting of venous CO₂ into the systemic circulation is rarely sustained with a stable RER for more than a minute or two during exercise because these patients become CO₂-unloaded and acutely alkalemic. With hyperventilation and no other disease, SpO₂ does not decrease and MRT for VO₂ is normal, in contrast to PPH.2,3

With a low anaerobic threshold, the development of lactic acidosis at a low WR causes PETO₂, Ve/VCO₂, and RER to
continue to increase, in contrast to the abrupt but stable increases seen with an EIS. Evidence that the anaerobic threshold is reached later during exercise confirms that the earlier changes are due to an EIS.

Validity of Patient Groupings
As demonstrated in Figures 4 and 5, the absence of a detectable PFO at rest does not preclude right-to-left shunting during exercise. Because shunting is a dynamic process

dependent on transient pressure differentials, we did not expect to find an absolute concordance between the resting echocardiograph and CPET evidence of an EIS. It is unlikely that even the most sensitive echocardiographic methods at rest would detect PFOs in the 39 patients who were graded as EIS+ or that the 18 patients who had a detectable PFO by echocardiography would not also have right-to-left shunting during exercise. Therefore, we used both CPET and echocardiographic findings to define and compare the shunt and no-shunt groups.

Incidence of Right-to-Left Shunting

The high sensitivity, specificity, positive and negative predictive values, and accuracy comparing CPET with echocardiography (Table 3) demonstrate the utility of the gas exchange method in EIS detection. With respect to intraobserver variability, it seems that using tabular data to detect small changes increased sensitivity but slightly decreased specificity.

Ultimately we found, using both the resting and exercise measurements of our 71 PPH patients, that in addition to the 18 patients who were both PFO+ and EIS+ by all graders, 9 more patients (6 by echocardiography and 3 by distinctive late-exercise changes) had convincing evidence of a right-to-left shunt either at rest or during exercise (Figures 4 and 5). Five more may have had right-to-left shunting by CPET criteria (Figure 5). Thus, the incidence of right-to-left shunting through a PFO in our PPH patients during exercise seems to be 38% to 45%.

An autopsy study of 965 “normal” hearts showed a PFO incidence of 20% to 34%, with decreasing PFO frequency but increasing size with advancing age.16 Using Valsalva maneuvers during echocardiography, the incidence of PFO in normal subjects is reported at just 5% to 18%,7–10 in part because most normal adults do not shunt blood through their PFO and also because the Valsalva maneuver does not always produce sufficient interatrial pressure differences to cause shunting. An 18% echocardiographic incidence of PFO or interatrial defects was detected in a recent

series of untreated PPH patients. Stroke patients have a higher incidence of PFO (as high as 78% in young patients with cryptogenic strokes, possibly due to paradoxical emboli). The relatively high EIS+ incidence in our series argues that chronic pulmonary hypertension also increases the potential for shunting through foramina ovale that might otherwise remain undetected and that such shunting may favor an increased survival.

Implications
CPET is a safe, noninvasive, cost-effective, and easily repeatable method for assessing PPH patients and detecting an EIS. The 9-panel graphic array (Figure 1) not only helps in the general interpretation of CPET studies, but also assists in the recognition of the distinctive gas exchange pattern of an EIS.
